ABSTRACT

A new microfabrication technology for high-aspect-ratio Parylene structure is developed for soft spring applications and applied to in-plane seismometer which covers low frequency (< 1Hz) and small acceleration range. Parylene beams having 10-40 \( \mu \text{m} \) wide and an aspect ratio of 10-30 were successfully fabricated. Since Parylene has a small Young’s modulus and is non-brittle material, high-aspect-ratio robust beam having spring constant on the order of \( 1 \times 10^{-3} \) N/m was realized. A prototype capacitive seismometer was also made, and its resonant frequency and noise spectral density was respectively measured to be 37Hz and 45 \( \mu \text{g} \cdot \sqrt{\text{Hz}} \). Since the Brownian noise is only 25 \( \mu \text{g} \cdot \sqrt{\text{Hz}} \), seismometer having much lower noise floor may be feasible using this new technology.

INTRODUCTION

For mechanical transducers, sensitivity to mechanical force should vary by orders of magnitude depending on the direction. The structure should be soft in the direction of interest, but it should be very rigid to other two perpendicular directions to minimize mechanical cross talk. Therefore, fabrication technologies for high-aspect ratio structures (HARS) attract much attention in the MEMS field.

The most straightforward approach for HARS is to use deep reactive ion etching (DRIE) of silicon substrate such as the Bosch process [1]. HEXSil[2, 3] and HARPSS[4] are also proposed for high-aspect poly-silicon structures, where deep trenches are refilled with polysilicon. However, both single crystal silicon and polysilicon are brittle so mechanical failure is of concern. High-aspect ratio metal structures can be fabricated by LIGA[5] process, but it requires X-ray, which is generally a much more complex process. Moreover, the existing technologies all use material having a large Young’s modulus \( >100 \text{GPa} \), submicron lithography is often required to realize soft springs [6].

The objective of the present study is then to develop a new microfabrication technology to produce high-aspect ratio Parylene beams with small spring constant. The advantage of using Parylene is twofold. First, Parylene has a small Young’s modulus (~4GPa), which makes easy small spring design. Secondly, Parylene is a non-brittle material with a large linear-elastic range (yield strain~3%), which allows large deflection without failure. Here, we present the first in-plane seismometer using the Parylene high-aspect ratio beams.

FABRICATION

The major process flow for the high-aspect-ratio Parylene beam fabrication is shown in Fig. 1. The process starts with 4” silicon wafers having 2 \( \mu \text{m} \) thermal oxide. The oxide is patterned on the front side, and the substrate is DRIE etched with 400 \( \mu \text{m} \) deep trenches. The trenches are used as Parylene mold and their depth defines the desired height of the beams. A prototype capacitive seismometer was also made, and its resonant frequency and noise spectral density was respectively measured to be 37Hz and 45 \( \mu \text{g} \cdot \sqrt{\text{Hz}} \). Since the Brownian noise is only 25 \( \mu \text{g} \cdot \sqrt{\text{Hz}} \), seismometer having much lower noise floor may be feasible using this new technology.

PARYLENE HIGH-ASPECT RATIO SPRING

Figure 2a shows an SEM image of the 30 \( \mu \text{m} \)-width trench after the etch back of Parylene film. Clearly, the Parylene deposition is conformal, and film thickness inside the trench is almost uniform. Also seen is small void inside, which is caused because the top part of the trench is sealed at the early stage of the deposition. If desirable, this void can be completely eliminated with an etchback and a second Parylene deposition (Fig. 2b).
beam having 30µm in width, 400µm in height, and 2.5mm in length. Triangle-shaped trench etched into the substrate works well for the anchor. Figure 3b shows a magnified view of a pendulum structure with a 10µm-wide beam (aspect ratio 30). The device was fixed onto a goniometric stage and the deflection of the pendulum due to the gravity force was measured by changing the tilt angle. Figure 4 shows the deflection of the beam versus the gravity force. The spring constant is as low as 0.0059 N/m, a value smaller than the designed value. This is partially because the second deposition of Parylene was not made for this test device, and the cross section of the beam is U-shaped as shown in Fig. 2a. It is noted that this soft spring is also robust and will not fracture even by shaking vigorously.

In order to study the dynamic response of the Parylene beams, a 1.75×1.75mm silicon seismic mass supported with two Parylene leaf springs (Fig. 5&6) was fabricated. The beams are 20µm in width and 400µm in height. The device was glued onto a loud
eral hours, which corresponds to about $2 \times 10^6$ cycles.

**PROTOTYPE IN-PLANE SEISMMETER**

In order to demonstrate the advantage of the Parylene high-aspect ratio beam, prototype of in-plane capacitive seismometer was designed and fabricated. As shown in Figs. 8a&b, the seismic mass (9.4 $\times$ 6 mm) is supported with four leaf springs and the electrical contact was made through a Cr/Au/Cr layer (100Å/2000Å/100Å) thermally-deposited on the top of the 20µm-width beams. Another Parylene film of 2µm in thick-
ness was deposited on the top of the electrode as the protection layer. The resistance between the substrate and the grid electrodes is 60 Ω. The resonant frequency measured is 37 Hz, which is in good agreement with the designed value of 35 Hz. The displacement of the seismic mass was measured by the capacitance change.

Counter electrodes were patterned on a glass wafer and attached to the silicon substrate with a gap of about 100 µm as shown in Fig. 8c. Figure 8d shows our early prototype seismometer, in which a differential-type readout IC (MicroSensors Inc., MS3110) having a low noise floor of 4 aF Hz / is used. Figure 9 shows the static response of the seismometer using a tilt experiment. The sensitivity of this prototype is only 0.221 V/g, which is 5 times smaller than the designed value. This is probably due to the parasitic capacitance, since the gap between electrodes is not small enough when compared with the electrode width. Since the noise floor of the voltage output is about 10 µV / √Hz, the noise spectral density is 45 µg / √Hz. Note that, our second generation prototype under development has lower resonant frequency, improved electrode design, and better readout IC settings, and the noise floor of about 1 µg / √Hz can be expected with a bandwidth of 20 Hz.

The Brownian equivalent acceleration noise \( g_{n,B} \) is given by

\[
g_{n,B} = \frac{1}{g} \sqrt{\frac{8 \pi k T f_{\text{res}}}{M Q}} \left[ \frac{g}{\sqrt{\text{Hz}}} \right], \tag{1}
\]

where \( k \), \( T \), and \( M \) are respectively the Boltzmann constant, temperature, and the weight of the seismic mass[7]. In the present seismometer, \( f_{\text{res}} = 37 \) Hz, which is the lowest resonant frequency among MEMS seismometers ever built. Moreover, the mass \( M = 66 \) mg is much larger than the mass of previous seismometers.

Thus, \( g_{n,B} \) given by Eq. (1) is as low as 25 ng / √Hz, and three orders of magnitude smaller than the noise floor measured. Therefore, the noise level of the present seismometer is not be limited by the Brownian noise, and there exists much room to improve its sensitivity.

CONCLUSIONS

A new high-aspect-ratio Parylene beam technology is developed. Soft but robust spring is successfully fabricated and fully characterized by a series of experiments. Early prototype of capacitive in-line seismometer having a record-low resonant frequency (37 Hz) was also made. The noise floor is found to be 45 µg / √Hz, and is not limited by the Brownian noise.
